NONLINEAR ELECTROMAGNETIC ACOUSTIC TESTING METHOD FOR TENSILE DAMAGE EVALUATION
Tensile damage behavior of a nonlinear longitudinal wave is investigated, and from an experimental perspective, this research demonstrates the feasibility and robustness of the noncontact EMAT method for nonlinearity measurement with a longitudinal wave.

By ZHICHAO CAI, HAO CHENG, and CHENGCHENG LIU

This paper describes an approach for measuring material plasticity using contactless electromagnetic acoustic method. Harmonic generation from noncumulative fundamental longitudinal wave in specimen is studied based on numerical method, and the contribution to harmonic generation from tensile damage is shown to be higher than that from a geometric factor; more serious damages increase the amplitude of second harmonics. These two experimental setups (nonlinear piezoelectric method and nonlinear electromagnetic acoustic method) are used to assess the relative nonlinearity parameters of tensile damage of five aluminum alloy specimens along the thickness direction, and the proposed technique is as effective with the traditional nonlinear piezoelectric method. This result demonstrates that the ultrasonic nonlinear parameter can represent tensile damage with ultrasonic nonlinear parameter by noncontact electromagnetic acoustic method.

1. INTRODUCTION

The application of ultrasonic waves in engineering structure now is a critically significant method in nondestructive testing (NDT) and structural health monitoring (SHM). With the latest developments in image processing and mathematical and computer modeling, more sensitive and economical ways of looking at materials and structures have become possible when compared to the other inspection techniques [1]. The traditional ultrasonic testing method is based on the linear theory and depends on measuring particular parameters, including the size, the orientation, the location of crack, the acoustic velocity, the attenuation, and the transmission and reflection of ultrasonic wave to detect damage [2]. However, traditional linear ultrasonic methods detect cracks or features based on the order of the wavelength of the ultrasonic wave. They are sensitive to microstructural features that are orders of magnitude bigger than the wavelength, but linear ultrasonic testing is not sensitive to early-stage degradation and microcrack of materials without diffraction and attenuation effect. Therefore, the detection of early damage becomes an issue and advanced ultrasonic testing becomes strongly needed. In addition, the development of the ultrasonic testing method is a challenging task that should have several crucial applicative functions such as online evaluation, condition-based maintenance, fitness determination for service and remaining useful time, less cost and labor, required baseline, and required environmental data compensation methods. The nonlinear ultrasonic method has a powerful ability to characterize microstructural features in materials. The basic physical mechanism of higher harmonic generation, subharmonic generation, shift of resonance frequency, and mixed frequency response are introduced with applications to evaluation of microdamage. These effects are quantified with the measured acoustic nonlinearity parameter (ANP), which is caused by the interaction of a sinusoidal wave and microstructural features such as microcracks, precipitates, creep, fatigue, and plasticity [3–8] (i.e., features at the micron scale and below), and the ANP is a powerful indicator of the material state.

Currently, a number of investigators have applied nonlinear ultrasonic techniques to assess the damage in different metallic alloys such as early fatigue damage in Ti-6Al-4V specimens [9], heat-treated Cr-Mo-V steel [10], hardening in ASTM A710 steel [11], nickel-based superalloy samples under monotonic and fatigue loading [12], and plastic deformation in AL 1100-H16 alloy [13]. It is noted that the ANP, which is based on the fundamental and second harmonics, significantly changes with the damage.

The most commonly used nonlinear wave technique uses through-transmission bulk waves, which is applied in the field since access to both sides of the specimen is required. Longitudinal waves have the advantage, as compared to shear waves [14], of transferring energy to second harmonics; shear waves transfer energy to third harmonics. Therefore, it is more possible for nonlinear longitudinal wave to assess the material inner damage. In addition, nonlinear Rayleigh surface and Lamb waves are widely used to represent the material superficial or integral damage, which, with a smaller diffraction and attenuation, effects with long distance traveling.

However, most nonlinear ultrasonic applications detect material characterization and the existence of minute defects by piezoelectric ultrasonic method and a high nonlinear efficiency of a liquid coupling medium. The piezoelectric ultrasonic method is not appropriate for testing in extreme conditions and rough testing surfaces, and coupling medium affects the scan efficiency of the specimen to be measured. Therefore, noncontact ultrasonic testing method has a better application prospect. Sebastian et al. present noncontact an air-coupled ultrasonic technique for a nonlinear Rayleigh surface wave measurement of the relative nonlinearity parameters of two aluminum alloy specimens AL2024-T351 and AL 7075-T651 [15], but the ultrasonic conversion efficiency is not enough with the acoustic impedance mismatch. A study of Liu et al. makes use of the nonlinear laser ultrasonic method to perform fatigue crack measurements [16]. However, the laser ultrasonic method suffers from variations in optical reflectivity and is only feasible for specimens with highly reflective surfaces.

An electromagnetic acoustic transducer (EMAT) is a kind of sensor that can excite and receive ultrasonic waves without coupling agent. The EMAT can be designed to generate and measure the desired mode of elastic waves on the basis of the contactless coupling mechanisms. Various propagation modes can then be used to meet...
2. PRINCIPLE

The principle of the electromagnetic-acoustic coupling process is the elastic response to periodic surface stresses that arise from Lorentz forces. An alternating current with the driving frequency \( f \geq 20 \text{ kHz} \) is applied to the spiral coil of the electromagnetic acoustic transducer. The dynamic magnetic field beneath the meander coil will be induced by the alternating current (within the electromagnetic skin depth). Generally, both the static magnetic field and the dynamic magnetic field will contribute to the Lorentz force occurring in skin depth. Generally, the skin depth is far less than the acoustic wavelength. Thus, the Lorentz force occurring within the skin depth can approximately be regarded as a shear stress exerted on the surface of the specimen, and the surficial stress can be regarded as an excitation source for the generation of a series of ultrasonic modes. In other words, the acoustic fields (the mechanical displacement) are generated by the Lorentz surface stress.

We consider nonlinear ultrasonic technique where the received signal is not at the frequency of the exciting current, and metallic material is treated as weakly nonlinear elastic because the amplitude of the signal received at higher harmonics is very small relative to the excitation, then harmonics can be generated notably at twice the excitation frequency.

The Lagrangian formulation from continuum mechanics is exploited using the Green-Lagrange strain tensor \( E \) along with the first Piola-Kirchhoff stress tensor \( T_1 \) and second Piola-Kirchhoff stress tensor \( T_2 \). \( E \) is related to the displacement vector \( u \), for simplicity, and the gradient of the displacement vector \( H \). And the following relations exist between the above quantities [25, 26].

\[
E = \frac{1}{2} (H + H^T + H^T H), \tag{1}
\]

where the linear strain is \( E^l \), which is related to the action of linear ultrasonic.

\[
E^l = \frac{1}{2} (H + H^T). \tag{2}
\]

Comparing Equation 1 with Equation 2, the existence of the second-order term \( H^T H \) is the main reason of nonlinear stress-strain, which includes geometric nonlinearity and material nonlinearity.

The stress-strain relation of higher harmonic generation for a hyper-elastic material is obtained from the nonlinear governing equations of Murnaghan model, which has a qualitative description of an harmonic vibration, and the strain energy function \( W(E) \) is

\[
W(E) = \frac{1}{2} \lambda (\text{tr}(E))^2 + \mu \text{tr}(E^2) + \frac{1}{3} (1 + 2m)(\text{tr}(E))^3
- n (\text{tr}(E)^2 - \text{tr}(E^2)) + n \text{det}(E), \tag{3}
\]

where \( I, m, n \) and \( \lambda, \mu \) are Murnaghan constants, and \( \text{tr}() \) and \( \text{det}() \) denote the trace and the determinant, respectively, of the bracketed tensor. The first Piola-Kirchhoff stress tensor and the second Piola-Kirchhoff stress tensor are obtained using

\[
T_1 = (I + H) T_2, \tag{4}
\]

\[
T_2 = \frac{\partial W(E)}{\partial E}, \tag{5}
\]

where \( I \) is the second-order identity tensor. And \( T_1 \) can be decomposed into linear and nonlinear components. Then the equation of motion in the reference configuration can be written as

\[
\nabla \cdot T_0 + \rho_0 \cdot \dot{b} = \rho_0 \ddot{u}, \tag{6}
\]

\[
b = b_{L,s} + b_{L,d} = J_c \times B_s + J_e \times B_d, \tag{7}
\]

where \( \rho_0 \) is the mass density, \( \ddot{u} = \delta^2 u / \delta t^2 \), and \( b \) is the Lorentz force which is the action of magnetic field (including the static magnetic field \( B_s \) and the alternating magnetic field \( B_d \)) and eddy current. The calculated Lorentz force is then applied to the elastodynamic equation as a body load. The acoustic wave passes the material boundary and creates dynamic electromagnetic fields in a conductive material exposed to a steady magnetic field, which then can be detected by a received EMAT. The inverse effect applies whereby the acoustic wave forces the charged particles to move with the aid of the magnetic field of permanent magnet bias. The dynamic electric field induced by the acoustic field in a specimen and the equation of receiving voltage \( E \) can be written as

\[
E = \frac{\partial u}{\partial t} \times B_s. \tag{8}
\]

3. NUMERICAL SIMULATIONS

In this section, the results are obtained from numerical simulations performed using COMSOL Multiphysics 4.3b, a commercial finite-element software. The schematic of the 2D model is shown in Figure 1. The modeling of Lorentz force generation process uses the AC/DC.
and Magnetic Fields module, and the modeling of propagation process uses the Structural Mechanics module.

The electromagnetic acoustic transducer consists of a coil that provides a dynamic current and a U-shaped magnet providing a horizontal static magnetic field. While in the nonferromagnetic material, the ultrasonic wave is generated by the Lorentz forces. The Lorentz force is the interaction of the magnetic flux density and the eddy current. Thus, the electromagnetic field and mechanical field are coupled together by Lorentz forces in the transduction area.

The permanent magnet material feature is Nd-Fe-B with a remanence of 1.4 T. The horizontal static magnetic field acts parallel to the coil along the x-direction; there are also x-direction Lorentz forces present that are usually much smaller than that the y-direction Lorentz forces. The spiral coil consists of 35 wires with a diameter of 0.5mm and entangles together closely. The lift-off distance between the coil and the tested aluminum specimens is 0.5mm. The exciting coils are carrying a current signal of $f = 500$ kHz. The thickness of the transduction area is five times the skin depth, and a low reflecting boundary is used to reduce back reflections from the edge of the remote interfaces.

The ultrasonic wave is generated on the transduction area. The simulations were carried out using the Murnaghan model for aluminum, and the material properties are tabulated in Table 1. Quadrilateral elements are used to discretize the magnet and coil with a maximum element size of 0.5mm; the transduction area and propagation area are divided into triangular elements with a maximum element size of 0.1mm and 0.2mm.

### 3.1. Ultrasonic Wave Generation

Due to the match of the coil and magnet, Rayleigh waves (R-Waves) travel along the surface, and simultaneously, the longitudinal waves (L-Waves) and shear waves (S-Waves) travel vertically into the specimen. Since S-Waves do not transfer energy to second harmonics [27], we investigate the nonlinear action of L-Waves and the contribution of the L-Waves, which are based on the x-direction Lorentz forces.

The x-component of the displacement is denoted by displacement $u_x$, the y-component is denoted by displacement $v_y$ and the direction of L-Waves vibration keeps consistent with the direction of L-Waves travelling. So displacement $v_y$ is only considered. Figure 2 shows the geometric dimension of the test specimen (100mm x 180mm) and the spread of ultrasonic wave inside the x- and y-coordinates which represent the cross-sectional displacement $v_y$ view of the wave modes propagating in two transmission cycles (from $t_0$ to $t_0 + 2T$). The R-Waves velocity $v_R$, the S-Waves velocity $v_S$, and the L-Waves velocity $v_L$ can be calculated by the time and the distance of flight between the two positions: $v_R = 2,915$ m/s, $v_S = 3,122$ m/s, and $v_L = 6,198$ m/s. Thus, with the increase of propagation time, the separation of various ultrasonic waves is more clear.

### 3.2. Nonlinear Ultrasonic Propagation

In typical EMAT configurations where the frequency is of the order from several hundreds of kHz to a few MHz, the amplitude of Lorentz force depends on the characteristic of the static magnetic field, the exciting current, the construction of the spiral coil, and the lift-off. In

order to eliminate the contribution of the second harmonic frequency due to alternating Lorentz force, the loading of body force is just applied by static Lorentz force $b_{L,S}$ in numerical model. So, the results were obtained for ultrasonic wave at fundamental frequency. Then we discuss the contribution of material and geometric nonlinearities to the second harmonic generation in the specimen. The displacement $v$ amplitude of L-waves should reach $1 \times 10^{-8}$ m, and the exciting current condition chosen is 150 A; some nonlinear effects are not easily decipherable at lower amplitudes. The results for three nonlinear mechanisms are presented in Table 2.

Figure 3 illustrates the normalized time domain signal obtained for the displacement $v$ at position (10 mm, -100 mm). It shows that the signals overlapped nearly for the three cases, and the difference is barely visible. So, the velocities of L-Waves are kept consistent in each. But in the frequency domain, as shown in the normalized logarithm processing of the fast Fourier transform (FFT) method in the figure, nonlinearity is evident from the nonlinear presence of zero-frequency and second harmonic components in the $v$ displacement of “N” and “G” cases. And the amplitude of the second harmonic generated in the “N” case is several times greater than that generated in the “G” case. This shows that the second harmonic generation is dominated by the material nonlinearity as opposed to geometric nonlinearity. The same explanations were adapted to obtain the main mechanism of zero-frequency components, which is dominated by geometric nonlinearity, while the “L” case shows only fundamental frequency without any frequency components.

The displacement $v$ were obtained at positions (10, -93.8 mm), (10, -100 mm), and (10, -106.2 mm) where the length of each propagation distance is one fundamental L-Waves wavelength. Figure 4 shows the normalized time domain signal and normalized logarithm processing of FFT. As predicted by theory, the amplitude of the second harmonic increases with the propagation distance. Then we discussed the effect of scaling higher-order elastic constants on the harmonic generation that increases with the degree of material damage.

Simulations for the “N” case used three different sets of higher-order elastic constants obtained by scaling Murnaghan constants by factors of 1, 2, and 4. Figure 5 shows the normalized time domain signal and normalized logarithm processing of FFT. As shown, the zero-frequency and second harmonic components are increasing with the factors. From another perspective, the degree of material damage increases with the nonlinear effects. In the following example, we present the results obtained for the second harmonic generation from the L-Waves at 500 kHz, 600 kHz, and 800 kHz in the “N” case. As shown in Figure 6, the same presence of zero frequency and second harmonic components in the various frequencies, and the normalized amplitudes of zero frequency and second harmonic components remain the same.

4. EXPERIMENTAL SECTION

4.1. Sample Preparation

Tensile specimens made of aluminum alloy 6061 were fabricated
for conducting the plastic deformation studies. The specimens were
tensile loaded to various levels of elastic-plastic strain under strain
control, as shown in Table 3. Among them, A₀ was an undamaged
specimen; A₁ was a specimen which produced in the elastic tensile
area; A₂ was a specimen that produced in the elastic-plastic critical
tensile area; A₃ was a specimen that produced in the plastic tensile
area, and A₄ was a fractured specimen. The noncontact nonlinear
characteristics were evaluated after unloading these specimens.

Nonlinear longitudinal wave was monitored at different posi-
tions along the length direction of tensile specimens for each sample.
Figure 7 shows the positions of measurement along the thickness
direction; each position is evenly spaced. The specimens are sub-
jected to a uniaxial tensile test. The deformation is such that the
material presents an elastoplastic behavior with nonlinear isotropic
hardening. When subjected to such large deformations, the speci-
men experiences a significant plastic deformation and necking in
its central cross section, and so nonlinear ultrasonic wave response at each position is
various for one loading condition.

4.2. Nonlinear Ultrasonic Measurement
Strategy
Figure 8 shows the nonlinear electromagnetic acoustic measurement. The nonlinear
response of tensile specimen aluminum alloy was excited by using a RITEC SNAP
RAM-5000 high power system (RITEC Inc., Warwick, RI, USA), and the high amplitude
sinusoidal tone burst inputs with a few number of cycles at a stable single frequency.

A pair of EMAT transducers are placed on
the double sides of the specimen (through
the thickness) as shown in Figure 9.
The EMAT transducer is mainly com-
bined by a coil and permanent magnet. A
toothpick is used to wind the copper wire
with a diameter of 0.1mm; each turn is
paralleled so closely that a large radius of
spiral coil is obtained. The spiral shape of
the EMAT coil is kept by laying an epoxy
adhesion bond. BNC cable is connected to
the spiral coil, and the permanent magnet
is put on top of the coil. The bulk EMAT is
facilitated after padding insulating poly-
mmer. The combination of a U-shape magnet
provides a horizontal-bias magnetic field,
and the spiral coil exerts high-frequency
current excitation, so the electromagnetic
force is mainly in a vertical direction; the
particle in the skin depth will be affected
by the electromagnetic force and produce a
high vertical frequency vibration. The high
vertical vibration producing ultrasonic
bulk waves would spread in the specimen.
One of the transducers acts as the trans-
mitter, sending the bulk wave (mainly, lon-
gitudinal wave) across the specimen, and
the other transducer plays the role as the
receiver based on the principle of electro-
magnetic induction. Hence, the longitudi-
unal wave propagates along the thickness
direction of the specimen, and the received
longitudinal wave would contain nonlinear information through
the propagation path.

However, since this measurement by noncontact method EMAT
has lower transduction efficiency, to avoid this inconvenience, addi-
tional devices are required to maintain the noncontact method by
impedance matching and a high-pass filter. The exciting current has

no window function in order to improve the exciting energy, which are from the high-power system to the EMAT transducers. Meanwhile, the exciting frequency should be considered by the designed EMAT frequency spectrum response curve as shown in Figure 10. These two EMAT transducers have the same designed size; thus, the exciting frequency has to be set 2.2 MHz, and the fundamental frequency 2.2 MHz and the harmonic frequency 4.4 MHz can be received at the peak frequency spectrum.

5. ANALYSIS

Nonlinear longitudinal wave measurement along the thickness direction of the Al 6061 plates are performed with the EMAT and PZT setup, and no near sound field effects are observed in this experimental setup with the suited selection of exciting condition.

5.1. Nonlinear PZT Measurement

The nonlinear parameter $\beta$ indicates that a linear relationship between the second harmonic amplitude $A_2$ and the square of the fundamental amplitude $(A_1)^2$. Since measurement of fundamental and second harmonic response by received ultrasonic sensor is in terms of the several voltages excitation, and $\beta$ can be predicted by the microplasticity model as a function of the tensile stress with few influence of different exciting frequencies [7], so a 5 MHz excited PZT sensor and a 10 MHz received PZT sensor were employed through the thickness direction to implement generated longitudinal wave.

Figure 11 shows a variation amplitude of $A_2$ with $A_1^2$ at the position 3 of specimen A0; the black spots are experimental data points at 10–50 level exciting voltages, and a linear fitting line of $A_2$ vs. $A_1^2$ for different driving voltages is clearly obtained, which means that the nonlinear parameter keeps constant for different voltages. The slope of this linear fitting line is the value of the nonlinear parameter $\beta_{p0}$ and $\beta_{p0}$ mainly includes material nonlinearity $\beta_{p0}$ and contact nonlinearity $\beta_{c0}$.

Consider the fluctuation of frequency response curve of PZT sensors (the frequency response at 5 MHz and 10 MHz points have disaffinity) and the influence of the nonuniform unit. Hence, the normalized nonlinear coefficient is $\beta_{p0}' = \beta_{p0}/\beta_{p0}$, that is,

$$\beta_{p0}' = \frac{\beta_{p0}}{\beta_{p0}}.$$

5.2. Compared with Nonlinear EMAT Measurement

In this EMAT measurement study, the lower transduction efficiency of EMAT is considered, as shown in Figure 12. EMAT has low energy converting efficiency and is sensitive to noise. The noise interference is mainly composed of continuous interference noise, paroxysmal interference noise, and electromagnetic noise, which are generated by the operation of the tested equipment and alternating electromagnetic fields in the limited space volume of the electromagnetic ultrasonic transducer. In order to realize the effective recognition of ultrasonic echo signal, the frequency-domain signal needs to be received with 40 dB attenuation of low-frequency stage and 60 dB amplification of high-frequency stage, where one can clearly find the contributions of the fundamental and second harmonic waves. Meanwhile, the frequency domain signal is filled with noise spectrum. To obtain the amplitudes of the fundamental and second harmonic wave components, Daubechies wavelet function and third wavelet packet decomposition levels were adopted to denoise as shown in Figure 12. In order to compare with the measurement by PZT sensor, and the nonlinear parameter $\beta_{p0}$ should be...
normalization processing by noncontact EMAT measurement, the normalized nonlinear coefficient $b'_{E0}=b_E/b_{E0}$.

Figure 13 shows the comparison of the relative nonlinear coefficients by the two methods. With the same loading, the variation tendency of the relative nonlinear coefficients stayed the same.

With elastic tensile loading ($F_{\text{max}} < 47.71$ kN), the relative nonlinear coefficients nearly keeps unchanged; thus, the elastic constant changes very little and increases rapidly when the tensile loading exceeds 47.71 kN at the position of 2, 3, and 4. Plastic deformation starts to exist at these positions; meanwhile, the relative nonlinear coefficients change very little at positions 1 and 5. It can be found that the plastic deformation is symmetrically distributed along the center specimen position (position 3) by tensile loading, and based on the metal necking effect, the plastic deformation is most notable at position 3. When the tensile loading exceeds 53.232 kN, the relative nonlinear coefficient drops rapidly, occurring with the more discontinuous area; at the same time, the plastic deformations at the position of 2 and 4 are still in the hardening stage and the relative nonlinear coefficients are still increasing.

It can be seen that the EMAT ultrasonic measurement is bigger than that of the PZT ultrasonic measurement. Namely, $b'_{E0} > b'_{p0}$, compared with what constitutes the two relative nonlinear coefficients, it is the contact nonlinearity (the influence of couplant and rough surface), which mainly causes the decrease in relative nonlinear coefficients. The result also shows that the change of the plastic nonlinearity on the plastic deformation can be measured using the proposed noncontact ultrasonic method, and the relative nonlinear coefficients measured by EMAT ultrasonic have potential applications in detecting variation tendency of plastic deformation under extreme environments.

6. CONCLUSIONS
In this article, tensile damage behavior of nonlinear longitudinal wave was investigated. From the numerical perspective, simulations of EMAT transduction and ultrasonic wave propagation were carried out in COMSOL Multiphysics 4.3b using the Murnaghan hyperelasticity model, harmonic generation from the fundamental longitudinal wave, while time domain signals show very small difference. The contribution of material nonlinearity, geometric nonlinearity, damage cased nonlinearity, and propagation distance cased nonlinearity to the harmonic generation is discussed. As the accumulated material damage is typically inferred from the nonlinear coefficient, which in turn depends on the higher Murnaghan constants and longer propagation distances, the exciting frequency is not inferred from the nonlinear coefficient.

From the experimental perspective, this research demonstrates the feasibility and robustness of noncontact EMAT method for the nonlinearity measurement with a longitudinal wave; thus, the surface condition of the specimen is relatively not important. The experimental setup provides an output signal with low SNR; meanwhile, wavelet denoising method can improve the SNR and extract nonlinearity information from measuring frequency signals. The results obtained in this research demonstrate that the noncontact, EMAT detection method provides potential field applicability for the in-situ measurements of the relative nonlinearity parameter in online structures. Further work needs to be done to identify the fatigue damage of ferromagnetic structure by EMAT method based on the magnetostrictive mechanism.
